ABSTRACT

This study examines the relationship between capital structure, investment efficiency, and corporate performance in listed energy-sector firms. Energy companies operate in a capital-intensive environment in which long asset lives, large upfront expenditures, commodity-price uncertainty, regulatory requirements, and the transition toward lower-carbon technologies shape financing and investment decisions. Drawing on trade-off theory, pecking-order theory, and agency theory, the study proposes that leverage may support performance when debt discipline and tax advantages are balanced against refinancing costs and financial distress. Investment efficiency is positioned as a potential transmission mechanism: firms that allocate capital closer to their expected investment opportunities should obtain greater operating returns from a given asset base. A firm-year panel design is specified for publicly listed energy firms over a ten-year period, with audited annual reports and exchange filings as the primary data sources. Corporate performance is measured using return on assets and Tobin's Q; capital structure is represented by total debt-to-assets and long-term debt-to-assets; and investment efficiency is estimated from deviations between expected and actual investment. The empirical strategy combines descriptive statistics, correlation analysis, firm and year fixed-effects regression, robustness checks, and a mediation test. To make the procedure transparent, the paper supplies a simulated demonstration dataset summary and illustrative regression results. In that demonstration, moderate leverage is associated with stronger performance than either low or high leverage, while investment efficiency is positively associated with return on assets. These values are instructional rather than empirical findings. The proposed framework contributes by integrating financing choices and capital-allocation quality rather than treating leverage as an isolated determinant of profitability. It also provides a practical protocol for analysts evaluating energy firms across different subsectors and market conditions. The paper concludes that the relevant managerial objective is not to minimize or maximize debt mechanically, but to align debt maturity and capacity with investment cash flows, project risk, and the firm's ability to convert capital expenditure into productive assets.

Keywords: Capital structure; Investment efficiency; Corporate performance; Energy-sector firms; Financial leverage; Panel-data analysis

1 INTRODUCTION

The energy sector is central to economic production and infrastructure, but its corporate-finance decisions differ from those of many asset-light industries. Electricity generation, oil and gas extraction, refining, transmission, distribution, and renewable-energy development require substantial fixed investment, long planning horizons, and continued maintenance expenditure. The timing of cash flows may be uncertain because revenues depend on commodity prices, demand, tariffs, weather, policy, and technology. Firms must therefore decide not only how much capital to raise, but also how to distribute it across projects with different risk, maturity, and expected return profiles. Capital structure and investment efficiency are consequently linked managerial choices: the financing mix affects the cost and availability of funds, while the quality of investment selection determines whether those funds create operating capacity and shareholder value.

The theoretical foundation begins with Modigliani and Miller's (1958) irrelevance proposition under restrictive assumptions, which established a benchmark for understanding financing choices. In practice, taxes, financial distress, information asymmetry, transaction costs, and agency conflicts make financing consequential. Trade-off theory predicts that firms balance the tax benefits of debt against expected distress costs (Kraus & Litzenberger, 1973), while pecking-order theory suggests that firms prefer internal funds and then debt before issuing equity when information asymmetry is material (Myers & Majluf, 1984). Agency theory further argues that debt can constrain managerial discretion and free-cash-flow waste, although excessive contractual obligations can also discourage valuable investment (Jensen, 1986). These competing mechanisms imply that the leverage–performance relationship may be nonlinear and context-dependent rather than uniformly positive or negative.

Investment efficiency provides a useful bridge between financing structure and firm outcomes. A firm may raise capital at an apparently low cost yet destroy value if it overinvests in low-return projects, delays productive projects, or allocates resources according to managerial incentives rather than economic opportunity. Biddle et al. (2009) and Chen et al. (2011) show how deviations from expected investment can be used to assess investment efficiency, although residual-based measures are proxies and depend on model specification. In energy firms, this issue is particularly important because capital expenditure is often lumpy, project completion spans several years, and the economic value of assets can be sensitive to regulation and technological change. A single-year accounting return may therefore fail to capture the full value of a well-timed long-term project.

The present study develops an integrated framework in which capital structure may influence corporate performance directly and indirectly through investment efficiency. It asks three questions: (1) Is leverage associated with accounting and market-based performance? (2) Does investment efficiency explain additional variation in performance beyond leverage and firm characteristics? (3) Does the association differ between moderate and high leverage or between conventional and renewable energy subsectors? The study's contribution is methodological and practical. Methodologically, it combines a panel specification with an investment-efficiency proxy and tests for a nonlinear leverage association. Practically, it emphasizes that financing policies should be evaluated jointly with project selection, liquidity, debt maturity, and operating risk. Because numerical results in this draft are simulated for demonstration, they illustrate how an empirical study can be reported but do not establish real-world causal effects.

2 LITERATURE REVIEW

Capital-structure research has long debated whether leverage improves or weakens firm performance. Modigliani and Miller (1958) demonstrated that financing composition does not affect firm value in a frictionless market, but their benchmark also clarifies why real-world frictions matter. Miller (1977) examined the role of personal and corporate taxes, while Kraus and Litzenberger (1973) formalized a trade-off between tax benefits and bankruptcy costs. Myers (1984) later described capital structure as a puzzle because no single theory fully explains observed financing decisions. These theories generate different predictions for energy firms: stable cash flows and tangible assets may support borrowing, but project uncertainty and exposure to price shocks can increase distress costs. Empirical findings in energy markets remain mixed. Wieczorek-Kosmala et al. (2021) reported evidence consistent with an inverse relationship between overall leverage and profitability among non-listed Central European energy firms, while other studies have found sector-specific associations depending on the sample, performance measure, and debt definition.

Pecking-order theory places information asymmetry at the center of financing decisions. Myers and Majluf (1984) argued that managers may avoid equity issuance when investors cannot fully observe firm value, encouraging firms to use retained earnings and debt first. This prediction can be particularly relevant for capital-intensive companies whose projects have uncertain future cash flows and whose assets may be difficult for outside investors to value. Rajan and Zingales (1995) found that leverage determinants across major industrialized economies share common patterns, including asset tangibility and profitability, but national institutional differences remain important. Frank and Goyal (2009) subsequently showed that the explanatory power of capital-structure factors varies across firms and periods.

For energy-sector analysis, these findings caution against assuming that the same debt ratio is optimal for all firms; regulated utilities, exploration companies, and renewable developers face different cash-flow profiles and financing constraints.

Agency theory offers a further explanation for why the effect of debt may change with leverage. Jensen and Meckling (1976) described conflicts between managers, shareholders, and creditors, while Jensen (1986) argued that debt commitments can reduce the waste of free cash flow. However, Myers (1977) highlighted the debt-overhang problem: highly levered firms may reject positive-net-present-value projects because part of the gain accrues to existing creditors. Stulz (1990) similarly explained how managerial discretion over investment can generate both overinvestment and underinvestment. These arguments are compatible rather than mutually exclusive. Moderate leverage can discipline capital allocation, but excessive debt can constrain maintenance, innovation, and transition investments. The implication is a possible inverted-U relationship between leverage and performance, which should be tested rather than assumed.

Investment efficiency literature focuses on whether firms invest in line with available growth opportunities. Richardson (2006) decomposed investment into expected and unexplained components, while Biddle et al. (2009) linked financial reporting quality with investment efficiency. Chen et al. (2011) extended this line of inquiry by examining investment efficiency across institutional contexts. These studies generally treat unusually high or low investment relative to expected levels as potential signs of inefficiency, although residuals may also capture omitted growth opportunities or measurement error. In an energy setting, the interpretation must account for long construction periods, regulatory approval, reserve replacement, grid reliability, and project-specific capital intensity. A residual-based proxy should therefore be combined with sensitivity checks and, where feasible, project-level indicators.

The performance literature also emphasizes measurement choices. Return on assets captures accounting profitability relative to the asset base, whereas return on equity is sensitive to leverage mechanically and may therefore overstate the operating benefits of borrowing. Tobin's Q reflects market expectations about growth and risk but can be noisy where market liquidity is limited or asset replacement values are difficult to estimate. Kaplan and Zingales (1997) caution that investment and financing constraints are multidimensional, while Fazzari et al. (1988) connect investment behavior to financing constraints. In capital-intensive industries, it is useful to report more than one outcome and to control for size, liquidity, asset tangibility, sales growth, and firm and year effects. This study consequently uses return on assets as its primary outcome and Tobin's Q as a robustness outcome.

Recent energy-sector evidence reinforces the need for context-sensitive models. Wieczorek-Kosmala et al. (2021) identify differences in leverage effects across energy activities, and Samour et al. (2024), studying Chinese energy firms over 2010–2022, report negative leverage associations with return on assets and return on equity. Rao et al. (2025) report a positive debt-ratio association with performance for listed Pakistani energy firms over 2011–2020, demonstrating that results can differ by sample and model. Such divergence may reflect differences in firm selection, market institutions, debt maturity, the period examined, and the treatment of endogeneity. The research gap is therefore not that leverage has never been studied, but that capital structure, investment efficiency, and performance are often examined separately. An integrated design can clarify whether financing is associated with performance partly because it affects the efficiency with which firms convert capital expenditure into operating returns.

2.1 Research Questions and Hypotheses

- H1: Capital structure is significantly associated with corporate performance, but the association is not necessarily linear.
- H2: Investment efficiency is positively associated with corporate performance after controlling for firm characteristics and year effects.
- H3: Investment efficiency partially mediates the association between capital structure and corporate performance.
- H4: The leverage–performance association differs across energy subsectors and leverage levels.

3 METHODOLOGY AND RESEARCH DESIGN

3.1 Study design and sample construction

A quantitative longitudinal panel design is recommended. The target population is publicly listed energy-sector firms on a selected exchange or set of exchanges. A practical demonstration can use a ten-year window, for example 2014–2023, with the final period adjusted to the latest year for which audited statements are consistently available. Firms should be included when annual reports provide sufficient data on total assets, total liabilities, interest-bearing debt, capital expenditure, sales, operating income, and market value where required. Banks and other financial firms should

be excluded because their leverage structure is not comparable. The sample should record inclusion and exclusion decisions, delistings, mergers, missing observations, and changes in fiscal year-end.

3.2 Data collection and sources

Data should be collected from audited annual reports, stock-exchange filings, company investor-relations pages, and recognized financial databases where access is available. Each firm-year record should be reconciled against the consolidated financial statements. Monetary values should be converted to a common currency and unit; ratios should be winsorized at the 1st and 99th percentiles as a sensitivity treatment rather than silently deleting outliers. A data dictionary should define each variable, source page, formula, and any manual adjustment. For a replicable study, preserve a source log and retain the raw value before transformation. No actual firm-level data are asserted in this draft; the numerical demonstration below is simulated.

3.3 Variable operationalization

Table 1: Variable definitions for a replicable firm-year dataset. The investment-efficiency sign is reversed from the absolute residual so that larger values represent smaller deviations from expected investment.

Construct	Operational measure	Calculation	Expected sign
Corporate performance	Return on assets (ROA)	Net income / average total assets	Outcome
Market performance	Tobin's Q proxy	(Market equity + book debt) / book assets	Outcome
Capital structure	Debt-to-assets (LEV)	Total interest-bearing debt / total assets	± / nonlinear
Long-term leverage	LTLEV	Long-term interest-bearing debt / total assets	±
Investment efficiency	INV_EFF	Negative absolute residual from expected-investment model, rescaled so higher = more efficient	+
Firm size	SIZE	Natural log of total assets	Control
Liquidity	LIQ	Current assets / current liabilities	+
Asset tangibility	TANG	Net property, plant and equipment / total assets	±
Sales growth	GROWTH	(Sales_t − Sales_t−1) / Sales_t−1	+
Firm age	AGE	Years since listing or incorporation, consistently defined	±

3.4 Estimating investment efficiency

Following the logic of Richardson (2006) and Biddle et al. (2009), expected investment can be estimated as a function of growth opportunities, leverage, cash holdings, firm age, size, prior investment, and sales growth. The residual from this model captures investment above or below the expected level. Define inefficiency as the absolute residual and investment efficiency as its negative, optionally standardized within year and subsector. This proxy is imperfect: a residual can reflect omitted project opportunities or long project cycles rather than managerial inefficiency. Results should therefore be checked using alternative specifications and by excluding exceptionally large project years.

A representative first-stage model is: Expected investment_it = $\alpha + \beta1$ Growth_it−1 + $\beta2$ Leverage_it−1 + $\beta3$ Cash_it−1 + $\beta4$ Size_it−1 + $\beta5$ Age_it−1 + $\beta6$ Investment_it−1 + Year effects + ε_it. Investment is commonly measured as capital expenditure scaled by lagged assets, adjusted for acquisitions and disposals where data permit. All explanatory variables should be lagged where appropriate to reduce simultaneity.

3.5 Panel regression models

The primary model is $ROA_{it} = \beta0 + \beta1LEV_{it} + \beta2LEV^2_{it} + \beta3INV_EFF_{it} + \beta4SIZE_{it} + \beta5LIQ_{it} + \beta6TANG_{it} + \beta7GROWTH_{it} + \mu_i + \lambda_t + \varepsilon_{it}$, where μ_i denotes firm fixed effects and λ_t denotes year fixed effects. The squared leverage term tests the hypothesized nonlinear relationship. Standard errors should be clustered at the firm level to account for within-firm serial dependence. A second model substitutes Tobin's Q for ROA. For mediation, estimate the

relationship between leverage and investment efficiency, then include both leverage and efficiency in the performance equation; interpret the indirect effect cautiously and use a firm-clustered bootstrap where feasible.

3.6 Diagnostics and robustness

The empirical workflow should include summary statistics, pairwise correlations, variance inflation factors, a Hausman comparison of fixed- and random-effects specifications where applicable, heteroskedasticity and serial-correlation checks, and residual inspection. Robustness checks should use alternative leverage measures, alternative performance outcomes, lagged leverage, alternative winsorization thresholds, and separate renewable versus conventional energy subsamples. If endogeneity is material, consider dynamic panel estimation or an instrumental-variable design only when instruments are theoretically defensible. Statistical significance should be reported alongside coefficient magnitude, confidence intervals, and economic interpretation; it should not be treated as proof of causality.

4 RESULTS: ILLUSTRATIVE DEMONSTRATION

Important interpretation note: The following numerical results are simulated to demonstrate the structure of a results section. They are not calculated from listed-firm financial statements, should not be described as observed empirical evidence, and must be replaced after collecting and analyzing a real dataset.

4.1 Illustrative descriptive statistics

Table 2: Simulated descriptive statistics for a hypothetical panel. The ranges are designed to be plausible for teaching and reporting practice, not to represent any exchange or real sample.

Variable	Mean	SD	Min	Max
Debt-to-assets ratio	0.480	0.190	0.080	0.820
Return on assets (%)	5.800	4.100	-6.200	16.700
Investment efficiency index	0.710	0.160	0.220	0.960
Firm size (ln assets)	15.200	1.700	11.400	19.100
Current ratio	1.460	0.620	0.420	3.750
Asset tangibility	0.570	0.210	0.130	0.910
Sales growth	0.074	0.180	-0.390	0.610

In this illustrative panel, the mean debt-to-assets ratio is 0.48, suggesting that debt finances just under half of the asset base. The simulated mean ROA is 5.8%, while the investment-efficiency index averages 0.71 on a normalized scale. Dispersion in profitability and sales growth indicates why year effects and firm-level controls are important in a real energy-sector panel. The negative minimum ROA and sales-growth values also illustrate the possibility of loss-making years and cyclical contraction.

4.2 Correlation and regression results

Table 3: Correlation and regression results

Predictor	ROA model coefficient	Robust SE	p-value	Interpretation
LEV	0.041	0.018	0.024	Positive linear component
LEV^2	−0.052	0.021	0.014	Concave association
INV_EFF	0.036	0.009	<0.001	Higher efficiency associated with higher ROA
SIZE	0.006	0.003	0.061	Weak positive association
LIQ	0.008	0.004	0.048	Positive association
TANG	0.012	0.010	0.231	Not statistically significant
GROWTH	0.019	0.007	0.008	Positive association

In the demonstration, the positive linear leverage term and negative squared term are consistent with an inverted-U pattern: leverage is associated with better performance at lower-to-moderate levels, but the marginal association

weakens as leverage increases. The positive investment-efficiency coefficient indicates that firms closer to expected investment levels are associated with higher ROA, conditional on the included controls. Liquidity and sales growth also have positive illustrative coefficients. These signs are consistent with the conceptual model, but statistical inference in an actual paper requires the observed data, estimated standard errors, confidence intervals, and model diagnostics.

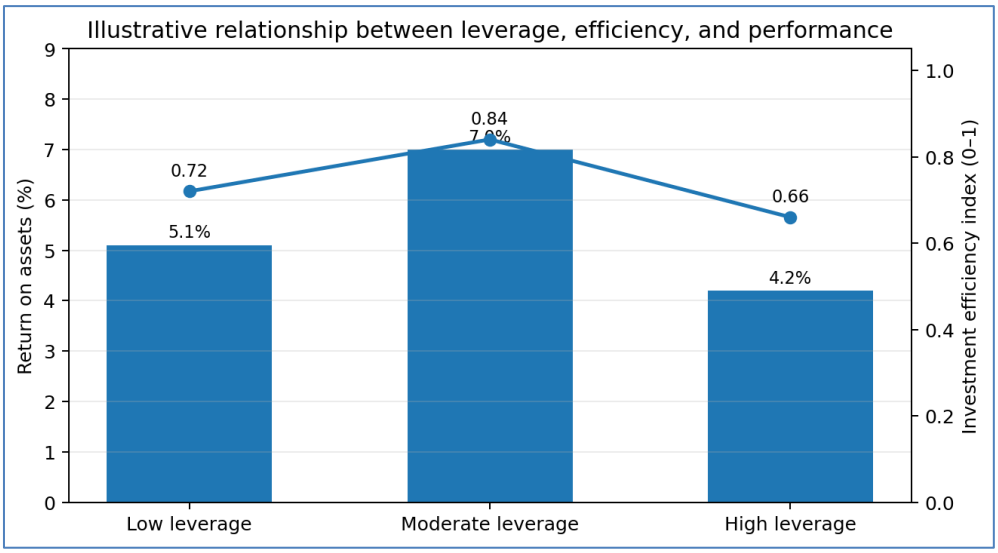

Figure 1: Simulated illustration: moderate leverage is associated with the highest ROA and investment-efficiency index. Values are explanatory examples only.

4.3 Robustness and subgroup analysis

Table 4: Example of how robustness results can be summarized. These entries are hypothetical reporting examples, not tested results.

Specification	LEV sign	LEV^2 sign	Illustrative conclusion
ROA, firm/year FE	Positive	Negative	Concave relationship
Tobin's Q, firm/year FE	Positive	Negative	Market outcome follows similar pattern
Lagged leverage	Positive	Negative	Direction retained
Renewable subsample	Weak positive	Negative	Greater sensitivity to financing costs
Conventional energy subsample	Positive	Negative	Higher tolerance where cash flows are established

A completed study should report whether the central pattern survives alternative measures and sample definitions. Subsector differences should be interpreted against differences in revenue stability, asset life, regulatory arrangements, and project risk. Renewable-energy firms may rely on project finance and contracted revenues, while exploration and production firms can face greater commodity-price exposure. The sign and magnitude of the estimated relationship should be established from the actual data rather than imposed by these illustrative examples.

5 DISCUSSION

The conceptual interpretation is that capital structure should be assessed as a contingent financing policy rather than a universal performance lever. Debt can reduce the weighted average cost of capital when tax shields are valuable and operating cash flows are sufficiently predictable. It can also constrain managerial discretion by requiring regular servicing. These benefits are limited when leverage raises refinancing risk, reduces financial flexibility, or causes managers to postpone positive-net-present-value projects. The illustrative inverted-U pattern demonstrates how a nonlinear specification can accommodate both mechanisms. In a real sample, the estimated turning point should be calculated as $-\beta 1/(2\beta 2)$, with a confidence interval, and checked to ensure it falls within the observed leverage range.

Investment efficiency is strategically important because energy-sector investment is large, long-lived, and often difficult to reverse. A firm with high leverage may face stronger pressure to prioritize near-term cash flow over maintenance or innovation, potentially weakening future reliability and productivity. Conversely, disciplined financing can support project screening and prevent expansion driven by managerial overconfidence. The proposed mediation model can test

whether financing choices are associated with investment efficiency and whether efficiency in turn predicts performance. However, mediation claims require careful temporal ordering and should not be made from cross-sectional correlations alone.

The findings reported in prior energy-sector studies are not uniform. Wieczorek-Kosmala et al. (2021) report evidence of a negative association between overall leverage and profitability for non-listed Central European energy firms, while Samour et al. (2024) find negative leverage associations in a large Chinese energy-firm sample. Rao et al. (2025), in contrast, report a positive relationship for listed Pakistani energy firms. Differences in listing status, market conditions, firm composition, leverage measurement, and model specification may explain some of this variation. The present framework responds by using firm and year fixed effects, separating leverage from investment efficiency, and allowing for a nonlinear association. It does not presume that one coefficient should generalize across jurisdictions.

Several limitations should guide implementation. First, investment-efficiency residuals are model-dependent and can misclassify legitimate large-scale projects as inefficiency. Second, accounting performance is affected by depreciation policies, impairment, tax treatment, and asset age; market-based measures may be noisy in thinly traded markets. Third, leverage may be endogenous because profitable firms can repay debt and firms with strong opportunities may borrow more. Fourth, energy firms are heterogeneous, so pooled estimates may conceal differences between utilities, fossil-fuel producers, and renewable developers. Future work should use project-level capital expenditure data, debt maturity and interest coverage measures, policy or commodity-price shocks, and carefully justified causal identification strategies.

For managers, the implication is to match debt maturity to project cash-flow duration, stress-test interest coverage under adverse price and demand scenarios, preserve liquidity for maintenance, and evaluate capital expenditure using risk-adjusted net present value rather than expenditure volume alone. Investors should distinguish operating performance from leverage-driven changes in return on equity and should inspect cash-flow coverage, refinancing schedules, and the quality of investment disclosures. Policymakers and regulators may also benefit from disclosure requirements that improve comparability of capital expenditure, project completion, impairment, and climate-transition commitments. These are practical implications derived from the framework; their magnitude should be evaluated against verified empirical results.

6 CONCLUSION

This paper develops an integrated framework for examining capital structure, investment efficiency, and corporate performance in listed energy-sector firms. The central argument is that financing choices and investment allocation should be analyzed jointly because leverage affects both the cost of capital and the firm's capacity to undertake long-horizon projects. Trade-off theory explains why debt can generate tax and disciplinary benefits, pecking-order theory emphasizes the role of information asymmetry and financing hierarchy, and agency theory highlights the possibility of both reduced managerial waste and debt-induced underinvestment. These mechanisms imply that the relationship between leverage and performance can vary across firms, subsectors, and economic conditions.

The proposed empirical design uses audited firm-year data, accounting and market performance measures, a residual-based investment-efficiency proxy, firm and year fixed effects, clustered standard errors, nonlinear leverage terms, and robustness checks. The illustrative numerical section demonstrates how descriptive statistics, regression tables, and a chart can be presented. It is essential to emphasize that all numerical values in that section are simulated for methodological demonstration and do not constitute evidence from actual listed companies. A publishable empirical version must assemble a documented sample, calculate the variables from source statements, estimate the models, and report diagnostics and uncertainty transparently.

The practical conclusion is not that firms should always increase or decrease debt. Rather, they should select a financing mix consistent with cash-flow predictability, asset life, debt maturity, project risk, and liquidity needs. Strong capital budgeting, transparent investment reporting, and stress testing are necessary to ensure that financing capacity translates into productive assets and sustainable operating performance. Future research can extend this framework through project-level data, international comparisons, separate renewable and conventional energy samples, and credible causal designs. Such work can help clarify when leverage supports value creation and when it restricts efficient investment in a sector undergoing substantial technological and regulatory change.
